Abstract. We report on the latest results in the search for positively charged strangelets from E864's 96/97 run at the AGS with sensitivity of about 8×10^{-9} per central collision. This contribution also contains new results of a search for highly charged strangelets with $Z = +3$. Production of light nuclei, such as ${}^6\text{He}$ and ${}^6\text{Li}$, is presented as well. Measurements of yields of these rarely produced isotopes near midrapidity will help constrain the production levels of strangelets via coalescence. E864 also measures antiproton production which includes decays from antihyperons. Comparisons with antiproton yields measured by E878 as a function of centrality indicate a large antihyperon-to-antiproton ratio in central collisions.

1. Introduction

Strangelets are small color-singlet hadrons with baryon number $A > 1$ which contain about equal numbers of u, d and s quarks. Many of the theoretical calculations[1, 2, 3] based on the phenomenological bag model suggest that Strange Quark Matter (SQM) might be metastable or even absolutely stable. Ultimately only experiments can prove their existence or nonexistence.

Relativistic Heavy Ion Collisions create hot and dense nuclear (or quark) matter, which offer a unique opportunity to search for strangelets in accelerator facilities[4]. The experimental signature of strangelets used to date is their low charge-to-mass ratio. This is based on the fact that strangelets have one more quark flavor with negative charge ($-\frac{1}{3}$) than the normal 2-flavor nuclear matters. Recent investigations[1] suggest that strangelets produced in heavy ion collisions might even be highly negatively charged.

There are three classes of strangelet production models in Heavy Ion Collisions: distillation of Quark-Gluon Plasma (QGP) scenario[8, 9], coalescence model[10], and thermal model[14]. The QGP distillation scenario assumes that the strangelet formation is a two-step process. It is creation of QGP followed by QGP decay into strangelet. These two processes are in the speculative stage[11]. Some estimations are available in reference [8, 13] in which the QGP is assumed to break up into small droplets before distillation. Coalescence models calculate the production of hyperfragments. The hyperfragments are formed from individual nucleons and they subsequently decay to strangelets provided that strangelets are more stable. A thermal model[14] need not discuss specific reaction mechanisms, since its major ingredients are thermal and chemical equilibrium.

To prove the existence of strangelet one needs to find the strangelet. But to prove the nonexistence of strangelet, we need to know the production mechanism well. Unfortunately, even the formation of QGP is yet to be seen. The measurement of antihyperon-to-antiproton ratio will help us understand the system better even within the framework of hot and dense nuclear matter while large antihyperon-to-antiproton ratio[15] is consistent with QGP formation. Measurements of production of light nuclei are keys to understanding the possible strangelet production via coalescence[10] and they also provide other important information about the colliding system[27].

This contribution presents recent results in the search for positively charged strangelet with E864 and discusses the significance of the results and their implications with the help of light nuclei results. The antihyperon-to-antiproton ratios or $(\bar{\Lambda} + \bar{\Sigma}^0 + 1.1\bar{\Sigma}^+)/\bar{p}$ vs. centrality implied from $\bar{p}$ measurements by E864 and E878 are presented as well.

2. E864 apparatus

E864 is an open geometry, high data rate spectrometer designed to search for strangelets[5, 6, 7] and measure the production of many particle species in high energy nucleus-nucleus collisions at the AGS. We can have two relatively independent mass measurements with the E864 apparatus(Fig 1) : the tracking system and the hadronic calorimeter. They identify particles and reject background powerfully with the confirmation of each other. The tracking system has two dipole analyzing magnets (M1 and M2) followed by three hodoscope planes(H1, H2 and H3). There are two straw stations (S2 and S3), each with three close-packed double planes. Each scintillating hodoscope plane has 206 vertical slats, and there are more than 1000 straw tubes in each straw plane. The tracking system measures momentum, charge and velocity (β) of charged particles with a mass resolution of about 3% in the region of interest. Charge misidentification is less than 1 in 10 billion due to three redundant charge measurements. There is an additional mass measurement from hadronic calorimeter[16] which has good energy ($\Delta E/\sqrt{E} = 0.344/\sqrt{E} + 0.035$) and time ($\sigma_t \simeq 400ps$) resolutions. It is made of 754 towers of scintillating fibre embedded lead. A vacuum tank is along the beam line to reduce the background from beam particles interacting with air. The total length of the apparatus is about 28 meters. The incident beam is 11.5GeV/c Au beam on Pt target with 60% interaction length. The spectrometer fields of M1 and M2 are set to their highest field +1.5T to reduce background (sweep out high Z/A particles) and achieve best tracking resolution for positively charged strangelets.

The trigger consists of good beam definition, a multiplicity requirement[17] and a level II high mass trigger[18]. Only events of the 10% most central collisions are collected since strangelets are most likely to be produced in central collisions. High sensitivity and open geometry are keys of E864. We achieve the high sensitivity by a high-mass level II trigger – Late-Energy Trigger (LET). There is a two-dimensional (Energy and TOF) programmable lookup table for every calorimeter channel to setup for different topics. The LET rejects those events without any high mass candidate and achieve a rejection factor of about 70 while maintaining good efficiency ($\gtrsim 85\%$) for high masses. There are about 200 million LET events or 13 billion 10% most central events sampled in the whole data set for positively charged or neutral strangelet searches.

Offline cuts are used to further refine the candidate selection. For any particle, tracking mass and calorimeter mass have to be consistent with each other. These

confirmations are performed by energy and TOF consistency cuts. A upper limit cut on particle velocity (β) is used to maintain good mass resolution and clean up the background since σ_m/m scales with γ^2 . Tracking χ^2 and shower quality cuts are studied extensively.

3. Results

3.1. Strangelet searches

We have conducted the full analysis of 1996/97's '+1.5T' data set for strangelets with charge=+1, +2, +3.

There are two classes of background which we have to deal with. The background in the tracking system is the result from multiple scattering and neutron-proton charge exchange interactions. Fluctuations of energy measurements and overlapping showers are background in the calorimeter measurements. These two background sources are relatively independent. Simulations showed that we are able to achieve a rejection level of $< 10^{-10}$ per central interaction[20].

With all the cuts we used in analysis of data from the previous run[6, 21, 22], we observe 3 candidates with mass between 5 and 10 GeV/c^2 . But when we check for additional evidence of double interactions using the calorimeter, we conclude that the 3 candidates are probably normal particles scattered and their showers in calorimeter are contaminated by a second interaction[19, 23]. The efficiency of this additional cut is about 85%. In fig 2, the mass measured from the tracking system of charge=+2 is plotted. It is clear that consistency cuts between tracking and calorimeter measurements and tighter β cut do clean up the spectrum. We clearly see a 6He peak but we do not see any 8He or exotic particles. We conclude that there is no candidate with $1.0 < y < 2.1$ and $m > 7GeV/c^2$. We extend our analysis to include $|Z| \geq 3$ particles and indeed we are able to see a clear 6Li peak. With a loose $\beta < 0.985$ cut, no particle with $m > 8GeV/c^2$ is found. However, when the limits are calculated, a tighter cut ($\beta < 0.972$) is used. An analysis with the looser cut is being carried out and should give slightly better limits.

Because of the finite acceptance, we choose the following production model to calculate the sensitivities and limits :

$$\frac{dN}{dydp_t} \propto p_t \exp\left[-\frac{2p_t}{\langle p_t \rangle}\right] \exp\left[-\frac{(y - y_{cm})^2}{2\sigma_y^2}\right] \quad (1)$$

where $\langle p_t \rangle = 0.6\sqrt{A}GeV/c$ is the mean transverse momentum, $y_{cm} = 1.6$ is the center-of-mass rapidity and $\sigma_y = 0.5$ is the standard width of the rapidity distribution of the produced strangelet. It is worth pointing out that because of the large rapidity and transverse momentum coverage, the results depend weakly on the model chosen. E864 is capable of detecting weak-decay strangelets with lifetime of about 50ns or greater.

We compute the limits at 90% Confidence Level (C.L.) for strangelets of $Z=+1$, +2 and +3 with mass between about 10 to 50 GeV/c^2 . These results represent the best limits at AGS energies[4]. Fig 3 shows the preliminary limits together with our previous results[6] and predictions from coalescence, QGP distillation and thermal model. Interpretations and implications of the results will be discussed in next section.

3.2. Light nuclei

In addition to searching for positively charged strangelet, we measure the production of light nuclei near midrapidity up to $A = 6$ in this data set. Fig 2 shows preliminary measurements of the yields of ${}^6\text{He}$ ($J^P = 0^+$) and ${}^6\text{Li}$ ($J^P = 1^+$). Together with the analyses of other E864 data sets[24, 25], we observe an exponential decrease of the yields of particle production as a function of nuclear number A near midrapidity (center of mass of the system). That is

$$\frac{dN_A}{dydp_t}|_{p_t \simeq 0, y \simeq 1.9} \propto (1/50)^A \quad (2)$$

This means that the penalty factor of adding a nucleon to a nuclear cluster is about 50 for all nuclei up to $A = 6$ near midrapidity at $p_t \simeq 0$. From this observation, one can make a naive model of the particle production, namely:

$$N_A \simeq 157 \times \left(\frac{1}{50}\right)^{A-1} \times \lambda_s^{|S|} \quad (3)$$

where 157 is the total number of initial protons, λ_s is the strangeness penalty factor [10, 26] and $|S|$ is the total strangeness in the ‘cluster’. This naive model assumes complete stopping and does not take into account the change of the spectrum with mass and the spin factor. But it describes the trend of the production level.

3.3. $\bar{p}$ production vs. centrality

E864 has previously measured $\bar{p}$ production in 10% most central collisions[15, 28, 22]. Additional minimum bias data were taken in the 1996/97 run with LET trigger. When the measured $\bar{p}$ production shown in Fig 4 is compared with that from E878[29, 15] in different centralities, we see a strong centrality dependence of the level of disagreement between the two experiment measurements. This can be explained by the enhancement of antihyperon production in central collisions, because E864 accepts all the $\bar{p}$ ’s from antihyperon ($\bar{\Lambda}, \bar{\Sigma}^0, \bar{\Sigma}^+$) decays while E878 accepts only a small fraction of them. Detail comparisons can be found in [15, 28, 22]. From the difference of the acceptance and difference of the detected $\bar{p}$ ’s, we compute the antihyperon-to-antiproton ratios $(\bar{\Lambda} + \bar{\Sigma}^0 + 1.1\bar{\Sigma}^+)/\bar{p}$ in each centrality bin, where acceptance and decay branching ratios are properly taken into account. In Fig 4, we plot the low edge of the ratios at 98% C.L. together with the most probable values of the ratios as a function of centrality. It reaches the most probable value of 3.5 and is higher than 2.3 at 98% C.L. in central collisions. The interpretation is quite consistent since the ratio in peripheral collisions is consistent with that of p+p collisions at similar energy. We are looking forward to the forthcoming direct $\bar{\Lambda}$ measurements [30] at the AGS.

4. Interpretation of Strangelet Limits

4.1. Coalescence and thermal models

Coalescence[10] and thermal[14] models predict the production of hyperfragments. It is noticed that [10] [14] overpredict the production of light nuclei [24, 25] and therefore we expect overpredictions of hyperfragment/strangelet production from these models.

From Equation (3) and our most probable sensitivity at low mass range ($1.4 \times 10^{-8}/2.3$), we can translate our limits per central collision to limits in baryon number

and strangeness content[7]:

$$A + (0.41 \times |S|) < 7.1 \quad (4)$$

where $\lambda_s = 0.2$ [26]. For any combination of A and S satisfying Equation (4), we have the sensitivity for strangelets produced by coalescence if they exist.

Another important message from Equation (3) is that it is very unlikely to produce a large strangelet in a normal medium. For example, production of an $A = 10$ and $|S| = 0$ object will be at the level of 8×10^{-14} per central collision. On the other hand, this implies that positively charged strangelets can be a possible clean signature of QGP formation[9] which will not be confused by normal nuclei or strangelets produced via 'coalescence'.

4.2. Distillation of QGP

Our limits largely rule out the predictions from [8] and are at the same order of or below predictions from [13] for $m \sim 10$. However, predictions listed from [13] are from their early predictions in which a QGP is assumed to happen in every central collision at the AGS energy and an optimistic mass formula is used. Further improvement in the mass formula[13] indicates that strangelets with low A ($\lesssim 20$) are unstable. Our limits are not sensitive enough to challenge the region where one might expect stability according to this model.

Our limits do constrain the sequence of QGP production followed by QGP distillation into strangelet in a model independent way[6]. For large strangelets which are predicted to be more stable, our data restrict these processes at the 90% confidence level as follows:

$$B(\text{Au} + \text{Pt} \rightarrow \text{QGP}) \times B(\text{QGP} \rightarrow \text{Strangelet}) \lesssim 8 \times 10^{-9}, \quad (5)$$

5. Conclusions and future prospects

In summary, we have found no evidence of positively charged strangelets produced in 11.5 GeV/c per nucleon Au+Pt collision and set a 90% confidence level upper limit of about 8×10^{-9} per 10% most central collision for $|Z| = +1, +2, +3$ strangelets over a wide mass range and with proper lifetimes of $\gtrsim 50 ns$. This represents the best sensitivity at the AGS energies. We have measured production of $A = 6$ nuclei near midrapidity and found that the penalty factor of adding a nucleon to a cluster stays at about 50. Comparisons of $\bar{p}$ measurements between E864 and E878 as a function of centrality suggest an enhanced antihyperon-to-antiproton ratio in central collisions.

In the near future, we will combine two data sets ('+1.5T' and '-.75T') together to improve our sensitivities.

The strangeness penalty factor for adding hyperon to a nuclear cluster has never been measured in high energy heavy ion collisions. We have collected about 250 million LET events (12 billion central events sampled). The unique high sensitivity and open geometry give us opportunity to measuring the production of ${}^3_{\Lambda}H$ and ${}^4_{\Lambda}H$ through their two-body mesonic decay channel[31]. There are also data available for studying nuclear resonant states, such as 5Li , 5He . With these new studies, we hope to better understand the dynamics of the high energy heavy ion collisions and provide more information for future experiments in searching for strangelets via coalescence.

Acknowledgments

We gratefully acknowledge the excellent support of the AGS staff. This work was supported by grants from the U.S. Department of Energy's High Energy and Nuclear Physics Divisions, the U.S. National Science Foundation and the Istituto di Fisica Nucleare of Italy.
